(Received 16 December 2014; accepted 11 March 2015; published online 20 March 2015)

We investigated the nature of transport and magnetic properties in SrIr0.5Ru0.5O3 (SIRO), which has characteristics intermediate between a correlated non-Fermi liquid state and an itinerant Fermi liquid state, by growing perovskite thin films on various substrates (e.g., SrTiO3 (001), (LaAlO3)0.3(Sr2TaAlO6)0.7 (001), and LaAlO3 (001)). We observed systematic variation of underlying substrate dependent metal-to-insulator transition temperatures ($T_{MIT}$) ~ 80 K on SrTiO3, ~90 K on (LaAlO3)0.3(Sr2TaAlO6)0.7, and ~100 K on LaAlO3 in resistivity. At temperature $300 \, K \geq T \geq T_{MIT}$, SIRO is metallic and its resistivity follows a $T^{3/2}$ power law, whereas insulating nature at $T < T_{MIT}$ is due to the localization effect. Magnetoresistance (MR) measurement of SIRO on SrTiO3 (001) shows negative MR at $T < 25 \, K$ and positive MR at $T > 25 \, K$, with negative MR $\propto B^{1/2}$ and positive MR $\propto B^{2}$ consistent with the localized-to-normal transport crossover dynamics. Furthermore, observed spin glass like behavior of SIRO on SrTiO3 (001) at $T < 25 \, K$ in the localized regime validates the hypothesis that (Anderson) localization favors glassy ordering. These remarkable features provide a promising approach for future applications and of fundamental interest in oxide thin films. © 2015 AIP Publishing LLC.

I. INTRODUCTION

Transition metal oxides (TMOs) forging transition from one electronic phase to another, have been long debated problem in condensed matter physics as they display a plethora of many unique phenomena including metal-insulator transition (MIT) in strongly correlated systems, high temperature superconductivity in layered cuprates, and colossal magnetoresistance (CMR) in perovskite manganites.1–3 From the prolonged list of transition metal oxides, specially perovskites, Ruddlesden–Popper (RP) phases of strontium iridates and strontium ruthenates, SrIrO3, SrRuO3 have characteristics that are very close to iridates and strontium ruthenate, SrIr0.5Ru0.5O3 thin films recently, efforts have been devoted to manipulating the magnetic T_C and to tuning the transport properties in SrIrO3 by replacing 4d Ru with 3d,4d transition metal elements.14–15 This replacement causes localized orbitals to hinder the hybridization of Ru orbitals and results in formation of spin clusters that affect both magnetism and transport. Recently, efforts have also been made to synthesize polycrystalline SrIrO3 by replacing SrRuO3 with 3d transition metals.16–17

Now, one of the most discernible questions from electronic point of view is what would happen if we replace the 4d Ru with higher quantum numbered 5d based transition metal Ir or vice versa; let us replace half of them and stay in the intermediate region for the time being. The consequences of replacing the 4d Ru with 5d-based transition metal Ir or vice versa might allow coexistence of two ground states (SrRuO3 and SrIrO3) and push the system into different state. In this standard picture, in terms of microscopic nature, 5d transition metals have wider d orbitals than do 4d transition metals, so replacing 4d element with 5d should increase the band width (W). This change might also affect the overall magnetism, because SrRuO3 has strong ferromagnetism of itinerant nature (band magnetism). Additionally, replacing 4d ruthenium (z = 44) with 5d iridium (z = 77) should increase SOC because SOC $\propto z^4$. The difference in transport and magnetism between SrIrO3 and SrRuO3 results from their different magnitudes of the effective interaction (W/W). Replacing the Ir4+ ions by Ru3+ ions, which have smaller

ionic radius than does Ir$^{4+}$, would change the $B-O-B$ bond angle; this distortion would then modify the overlap between neighboring $d$ orbitals mediated by oxygen $2p$ orbitals, thereby changing $W$ and enabling control of $U/W$. Also, an interesting observation would be how the MR behaves due to RuO$_2$ powder by a solid state reaction method. In general, thereby changing $W_{\text{d}}$ neighboring angle; this distortion would then modify the overlap between SrRuO$_3$, in which MR is negative. If the MR of the compound material undergoes switching, it might be useful in memory device applications. Also for application purpose, extending the list of bottom electrodes having structural compatibility with perovskites and perovskite related structures is useful for the creation of new functional oxide electronic devices.

The purpose of this work is to show that the perovskite thin film SrIr$_{0.5}$Ru$_{0.5}$O$_3$ (SIRO), which has characteristics intermediate between a correlated non-Fermi liquid state and an itinerant Fermi liquid state, favors correlated state from resistivity point of view, whereas magnetoresistance and magnetization measurement shows close resemblance to an itinerant electronic state.

II. EXPERIMENTAL METHODS

We used pulsed laser deposition (KrF laser; $\lambda = 248$ nm) to grow SIRO thin films from a polycrystalline target synthesized from a stoichiometric mixture of SrCO$_3$, IrO$_2$, and RuO$_2$ powder by a solid state reaction method. In general, during thin film growth, metastable phases can be stabilized, and key parameters such as band width, SOC, and correlation of the system can be tuned by external parameters by using lattice-mismatched substrates. We have attempted and succeeded to grow perovskite SrIr$_{0.5}$Ru$_{0.5}$O$_3$ thin films ($\sim$40 nm) on lattice-mismatched substrates (SrTiO$_3$ (001), (LaAlO$_3$)$_{0.3}$(Sr$_2$TaAlO$_6$)$_{0.7}$ (001), and LaAlO$_3$ (001)). The laser was operated at frequency 4 Hz, the substrate temperature was 680 °C, and oxygen partial pressure was 20 mTorr. After growth, all films were cooled down slowly (~7 °C/min) in same oxygen partial pressure to compensate for any oxygen deficiency. All the substrates, SrTiO$_3$ (001), (LaAlO$_3$)$_{0.3}$(Sr$_2$TaAlO$_6$)$_{0.7}$ (001), and LaAlO$_3$ (001) crystals, were treated prior to growth to produce atomically flat surfaces. (Henceforth these substrates will be designated as STO, LSAT, and LAO). X-ray diffraction (XRD) measurements were performed by the Empyrean XRD System from PANalytical. XE-100 Advanced Scanning Probe Microscope was used for surface topography. To check elemental distributions, we used secondary ions mass spectrometry (SIMS) with a primary beam source of O$_2^-$ with impact energy of 7.5 keV. Electrical transport measurements were performed using the four-probe van der Pauw geometry within 10 K $\leq$ $T$ $\leq$ 300 K range.

III. RESULTS AND DISCUSSION

At ambient pressure, SrIrO$_3$ and SrRuO$_3$ have different crystal structures. SrIrO$_3$ is of orthorhombic structure only at high pressure with a lattice constant of $a_c \sim 3.96$ Å, whereas SrRuO$_3$ has a GdFeO$_3$ type distorted orthorhombic structure with a lattice constant of $a_c \sim 3.93$ Å. Assuming that SIRO should be pseudo-cubic with 3.93 Å $\leq a_c \leq$ 3.96 Å, it would cause increase in compressive strain on the films as the substrate lattice constants decreases; (STO substrates: $a_c \sim 3.90$ Å; LSAT: $a_c \sim 3.88$ Å; LAO: $a_c \sim 3.78$ Å).

XRD measurements of the SIRO films on these substrates show the crystalline (001)$_c$ peak without any impurity or additional peaks (Fig. 1(a)). To further characterize the crystallinity of the films, ω scans (rocking curve) were performed; in the results (Fig. 1(b)) around the (002)$_c$ peak of SIRO films, the center positions of full width at half maximum (FWHM) coincided and made to zero value. It is seen from the figure that the FWHM is small (~0.06°) for films on STO and LSAT but becomes broad (~1.65°) for films on LAO. The dense twinning of the LAO substrate is probably

FIG. 1. (a) X-ray $\theta$–$2\theta$ scan results of SIRO films of thickness ~40 nm grown on SrTiO$_3$ (001), LSAT (001), and LaAlO$_3$ (001) substrates. (b) Rocking curves (ω scans) around the (002)$_c$ peak of SrIrO$_3$ films on three substrates are shown. Zero value of $\Delta$σ corresponds to the maximum peak position. (c) SIMS reveals homogeneity of the SIRO/STO films (inset: AFM image). (d) Reciprocal space mapping of the (103)$_c$ peak of SIRO/STO reveals that film is fully strained.
responsible for degrading the surface quality of film on LAO substrate; this kind of feature has also been seen in pure SrRuO$_3$ film grown on LAO substrate.$^{24}$ To confirm more about sample quality, especially in the SIRO/STO film (as magnetotransport and magnetization measurements were done in this film based on substrate’s popularity; shown later), we used SIMS depth profile analysis to check the distribution of the cationic elements within the films. The distributions of Sr, Ir, Ru and O were uniform over the whole film thickness at the resolution level of SIMS (Fig. 1(c)). Atomic force microscopy (AFM) revealed that all surfaces were flat with a roughness of $\sim$1–2 nm (inset, Fig. 1(c)). We have also measured the strain in the SIRO film grown on STO substrate utilizing reciprocal space mapping (RSM)—a pathway to extract the inplane and out-of-plane lattice constants as well as the amount of strain by mapping of symmetric and asymmetric Bragg peaks. The RSM result around the inplane $(103)_C$ reflection peak of the SIRO film (Fig. 1(d)) shows that the film and substrate are locked and the strain in the film is determined by the underlying substrate. From the RSM data, the calculated out-of-plane lattice constant of the SIRO film was $\sim$4.01 Å, which confirms overall inplane compression with out-of-plane lattice expansion of the film.

Measured electrical resistivity of the SIRO films deposited on the substrates under the same deposition conditions were affected by temperature (Fig. 2(a)). The transport properties of the SIRO films were sensitive to the underlying substrates, as transport in both parent compounds (SrRuO$_3$, SrIrO$_3$) depends on underlying substrates.$^{7,10}$ In all three cases, the SIRO displays a metallic characteristic (decrease of resistance with decrease in temperature), with a MIT at a certain temperature $T_{\text{MIT}}$ and then insulating characteristics below it (increase of resistance with decrease in temperature), down to 10 K. It is clearly seen that $T_{\text{MIT}}$ varied systematically from $\sim$80 K (for STO), $\sim$90 K (for LSAT), and $\sim$100 K (for LAO) depending on the underlying substrate (Fig. 2(a)). This trend suggests that the strength of disorder in these films changes as the lattice mismatch between film and substrate increases, due to thermodynamic tendency to minimize the strain energy. In parent SrIrO$_3$ film on STO, we also observed a MIT at $T = 50$ K and as well as more compressive strained films show fully insulating nature in resistivity related with localization effect.$^{10,25}$ To perform quantitative analysis of each resistivity curve and gain further insights, at first in the metallic regime, we attempted to fit the temperature dependence of the resistivity and fitted with typical formula: $\rho = \rho_0 + A T^{3/2}$ (Fig. 2(b)), where $\rho_0$ is the residual resistivity which signifies scattering due to disorder and $A$ is the temperature coefficient, which represent the scattering strength. Here to be stressed that this fit was similar to metallic resistivity fitting for parent SrIrO$_3$ on STO substrate, where we also observed a $T^{3/2}$ power law dependence, but was not similar to the $T^2$ (at $T < T_C$) or linear $T$ dependence (at $T > T_C$) of SrRuO$_3$ film.$^7$ Generally, contribution of the incoherent part of electron magnon scattering to resistivity shows $T^{3/2}$ dependent at low temperature as found by Mills et al.$^{26}$ Our resistivity data cannot be interpreted using the above conventional theory because the $T^{3/2}$ power law was observed over a rather high range of $\sim$80 K $\leq$ $T$ $\leq$ 300 K. Self consistent renormalization theory based on spin fluctuations also produces a $T^{3/2}$ power law in resistivity.$^{27}$ This explanation can also be excluded in our

![Figure 2](image.png)
system because it does not show any kind of long-range magnetic ordering (will be shown later). But, the resistivity fitting shows $\rho \approx 4 \times 10^{-8} \text{ cmK}^{-1.5}$, which is close to the value of $3-5 \times 10^{-8} \text{ cmK}^{-1.5}$, which is often found in other strongly correlated electron systems such as SrRuO$_3$ and CaVO$_3$.\textsuperscript{28} As the system goes through the transition to Mott Hubbard regime from the itinerant side or vice versa, the quasi-particle scenario breaks down and non-Fermi liquid resistivity ($\rho \propto T^{3/2}$) was predicted to be associated with scattering between localized electrons by locally cooperative bond-length fluctuations and itinerant electrons. Moreover, in the insulating region below $T_{\text{MIT}}$ (Fig. 2(c)), $\rho$ of the SIRO films scaled with the variable range hopping (3D-VRH) model in three dimensions (i.e., $\ln \sigma \propto 1/T^{1/4}$).\textsuperscript{29} In the insulating regime, the Anderson localization effect occurs with the possibility of magnetic clustering effect of Ru and Ir moments. Transport is then only possible by hopping of charge carriers between localized states; this restriction suggests that the increase in $\rho$ at $T < T_{\text{MIT}}$ is a result of Anderson localization due to disorder caused by the random distribution of Ir ions on the Ru sites and vice-versa. This increase in disorder strength with increasing compressive strain is quite possible and would increase $T_{\text{MIT}}$ in samples grown under large lattice mismatch as the compressive strain suppresses the hopping probability of charge carriers.\textsuperscript{30,25} The possibility that the increase in $\rho$ might be due to the magnetic impurity Kondo effect has been excluded because this Kondo effect can only be observable at the low temperature limit and our temperature limit is quite high with respect to that limit.\textsuperscript{30} Although identifying the exact mechanism for the MIT and systematic variation of $T_{\text{MIT}}$ on different substrates requires further investigations on microscopic level, the present resistivity data demonstrate that MIT in SIRO is quite sensitive to external perturbations. Also, we may emphasize that the residual resistivity ratio ($\text{RRR} \approx 1$) is rather small, so the systems are be regarded as bad metals, as is parent SrIrO$_3$.\textsuperscript{10,25}

Now, turning into another aspect of how applied external magnetic field ($B$) affects the resistivity (viz., magnetoresistance, MR) would be an interesting phenomenon to observe. At low temperature, SrRuO$_3$ shows negative MR. When subjected to a magnetic field, Ru moments become well-ordered along its easy axis and thus reduce the scattering, so MR becomes negative; this is a well-established physical effect in ferromagnetic metals.\textsuperscript{27} In contrast, SrIrO$_3$ shows positive MR when subjected to a magnetic field, and this response can be explained to result from the Lorentz contribution for fully metallic films.\textsuperscript{10} The three dimensional SrIrO$_3$ films with increase in resistivity also show positive MR, to which both correlation and disorder make important contributions.\textsuperscript{30} Despite the origin, a three dimensional SrRuO$_3$ shows negative MR, whereas a three dimensional SrIrO$_3$ film shows positive MR. SrRuO$_3$ also has much larger MR values than SrIrO$_3$; this difference implies that the magnetic field has much stronger effect on Ru spins due to its ferromagnetic nature than its counterpart of possible paramagnetic moments of Ir spins.

Therefore, we measured magnetoresistance with the applied magnetic field oriented perpendicular to the film surface. MR of SIRO at $T = 10$ K was negative for samples grown on all three substrates (Fig. 3). At a glance, it can be said that at low temperature, the applied magnetic field mainly aligns the Ru spins (either ferromagnetic-like or some kind of local ordering; glassy like) and thereby leading to a decrease of electron-spin scattering and to a negative MR. As said earlier, 4$d$ itinerant ferromagnetic Ru moments have much stronger effect than 5$d$ Ir moments on applying magnetic field, so MR remains negative, although its magnitude decreases due to competitive randomness of spin interactions.

To check how this competition is affected by temperature, we took one sample (film on STO because it is the most popular substrate used for thin film growth) and measured the temperature dependence of MR (Fig. 4(a)). As temperature increased, MR changed sign and became positive. While increasing the temperature further, MR diminishes as seen in both parent materials also. Clearly, there is a sign change in MR above $\sim 25$ K (Fig. 4(b)). Plots of $\rho$ vs. $T$ at magnetic strengths of 0 T and 9 T crossed at $T \geq 25$ K (Fig. 4(b), inset). Moreover, negative MR was found to be $\propto B^{1/2}$ (Fig. 4(c)); consistent with localization picture.\textsuperscript{31} In contrast, positive MR follows $B^2$ power law dependence (Fig. 4(d)); consistent with normal transport behavior. This observation suggests that as $T$ increases, the applied magnetic field mainly localizes an increasing number of 5$d$ moments by enhancing the exchange interaction between localized moments and itinerant moments, thereby resulting in formation of magnetic polarons, and consequent appearance of positive MR. Switching of MR observed in other materials has also often been related to magnetic scattering.\textsuperscript{32–34}

To get an intuition about magnetic ordering in SIRO/STO, magnetization measurement of SIRO/STO film was performed; this film did not show any long-range magnetic ordering in the measured temperature range; $10$ K $< T \leq 300$ K. This result is consistent with the lack of any twisting in the resistivity curve (Fig. 2(a)); this lack of twisting indicates the absence of long-range magnetic order. In the localization picture, it is quite natural that the randomness of Ir paramagnetic moments due to its extended 5$d$
orbitals affects the local environment of Ru atoms and leads to suppression of its long-range ferromagnetic state. But, even in this scenario, local ordering can occur at low $T$ and be attributed to local magnetic ordering (spin glass type: $T_{SG}$) as seen at $T \leq 25$ K (Fig. 5(a)). Although the moment of the film was very low (as expected for a system containing a 5$d$ element that has weak correlation) even at low temperature (with respect to parent SrRuO$_3$) and close to the noise level, but the clearly observable cusp at $T \sim 25$ K establishes the appearance of glassy like behavior. Similar features of glassy ordering were also reported in other systems. Possible origin of glassy magnetic ordering due to substrate has been excluded, because magnetization measurements on STO substrate show purely diamagnetic behavior. Therefore the coexistent tendency of localization-induced insulating nature in transport (Fig. 2(c)) and glassy ordering (Fig. 5(a)) validates with the hypothesis that Anderson localization effect strongly stabilizes spin glassy behavior while Mott localization tends to suppress it. Surprisingly, we did not observe any glassy features in SIRO films grown on LSAT or LAO substrates (Figs. 5(b) and 5(c)). Any long-range magnetic ordering or low-temperature spin-glass behavior might have disappeared with much small percentage of Ir doping on SrRuO$_3$. This explanation is plausible because the evolution of the magnetic phase diagram is different for films grown on different substrates, because they have different amounts of strain, and increasing disorder (which increases with the lattice mismatch) affects the magnetization. On this basis, the origin of negative MR at low $T$ for higher strained films could be due to localization effect associated with the increased random distribution of Ir ions on the Ru sites and vice-versa due to increased strain. Assuming the above scenario stands the test of time, to shed the light more, perhaps, the most important step would be to obtain detailed information on microscopic level. Currently, X-ray magnetic circular dichroism (XMCD) measurements are ongoing to investigate the exact nature of magnetic ordering and testify the role of each transition metal element.

![Graphs showing magnetic properties](image-url)
IV. CONCLUSIONS

We grew epitaxial SrIr0.5Ru0.5O3 thin films on various lattice-mismatched substrates (e.g., SrTiO3 (001), (LaAlO3)0.3(Sr2TaAlO6)0.7, and LaAlO3 (001)). The films showed systematic variation in metal-to-insulator transition temperature $T_{\text{MIT}}$ in resistivity $\rho$ ($T_{\text{MIT}} \approx 80$ K on SrTiO3, $\sim 90$ K on (LaAlO3)0.3(Sr2TaAlO6)0.7 and $\sim 100$ K on LaAlO3); this variation is associated with disorder caused by large lattice mismatch. The entire metallic regimes of $T$ followed a $T^{3/2}$ power law on all three films, whereas insulating regimes were consistent with a three dimensional variable range hopping model. Furthermore, all the films show negative MR at $T = 10$ K. MR switched from negative to positive as temperature increased above $\sim 25$ K for SrIr0.5Ru0.5O3 film on SrTiO3 substrate. This temperature was associated with the signature of spin glassy ordering ($T_{SG} \sim 25$ K), consistent with localization theory. Overall, switching of MR may provide new physical significances which can be used for novel technological applications in which coupling of two different ground states persist. In general, disorder related (quantum) phenomena have fundamental rich physical aspects and above results are elucidated following the basic principle from disordered physics perspectives. However, above explanations may not be conclusive enough and requires detailed microscopic analysis, experimentally as well as theoretically for deeper understandings, considering the role of each and every element. So, in future, it is highly desirable to grow fully atomically ordered layer-by-layer thin films, especially SrIrO3/SrRuO3 superlattices, to further unveiling of new emerging phenomena.
